Dermatophytes are the most common cause of superficial fungal infections in humans; *Trichophyton (T.) rubrum* is the most frequently isolated pathogen. In humans, dermatophytes are mainly confined to the stratum corneum, nails, and hair. Dermatophytes do not actively penetrate deeper than the basal layer. They rarely penetrate deeply into the dermis and cause invasive infections involving hair follicles; the dermis; subcutaneous tissue; and even internal organs, such as the lymph nodes, bone, and brain. Invasive dermatophytosis is typically associated with immunosuppression and lymphoproliferative disorders. Compared with immunocompetent patients, patients with immunosuppression have an increased risk of invasive dermatophytosis.
increased risk of invasive form transformation, owing to chronic infection resulting from a higher rate of recurrence and recalcitrance. Herein, we report an atypical presentation of deep dermatophytosis as multiple exophytic masses in the bilateral lower limbs.

CASE REPORT

A 71-year-old woman admitted for pneumonia was referred for an erythematous exophytic mass with multiple subcutaneous nodules on both lower legs (Fig. 1A). The initial skin lesion was detected on the left leg a month before referral, which subsequently spread to the adjacent tissue and the right leg. The patient had a history of rheumatoid arthritis and was treated immunosuppressants, such as tacrolimus, low-dose systemic steroid, leflunomide, and methotrexate, for more than 10 years. Furthermore, she had taken an antifungal medication for tinea pedis and unguium; however, she decided to discontinue the treatment.

A deep fungal infection was suspected based on her skin lesion and history. A skin biopsy was performed on her left lower leg. Histopathological examination revealed pseudoepitheliomatous epidermal hyperplasia with micro-abscess formation in the epidermis and diffuse granulomatous inflammation consisting of multinucleated giant cells, lymphocytes, neutrophils, and histiocytes in the dermis. Immunohistochemical staining with periodic acid-Schiff and Gomori methenamine silver revealed septate and branched fungal hyphae in the dermis (Fig. 2). Fungal cultures performed using biopsy

Fig. 1. (A) 71-year-old woman presented with multiple erythematous exophytic and subcutaneous nodules located on lower legs. (B) All lesions showed improvement after amphotericin B administration.

Fig. 2. (A) Microabscess, pseudoepitheliomatous hyperplasia in epidermis with dense mixed infiltration in dermis consisting of neutrophils, lymphocytes, histiocytes, multi-nucleated giant cell (H&E ×100) (B) Diffuse granulomatous infiltration with multi-nucleated cells, lymphohistiocytes, neutrophil in dermis (H&E ×400) (C, D) Septate, branching hyphae invading in dermis (PAS, GMS ×400)
Deep Dermatophytosis Presented as Multiple Exophytic Masses caused by *Trichophyton rubrum*

Tissue showed red-brown pigmentation, suggesting *Trichophyton* species infection (Fig. 3). A molecular approach was used based on the sequence analysis of ribosomal DNA (rDNA). *T. rubrum* was identified by phylogenetic analysis using internal transcribed spacer and large subunit (LSU) region sequencing of ribosomal RNA gene (Fig. 4).

Before the identification of the causative organism, the patient’s condition deteriorated because of septic shock. Amphotericin B was administered empirically for 6 days to prevent hematogenous dissemination, and the skin lesions resolved simultaneously (Fig. 1B).

**DISCUSSION**

Dermatophytes cause superficial infections of the skin and rarely cause deep infections invading the dermis in patients with acquired or innate immunosuppression. Most patients acquired immunosuppression are organ transplant recipients. However, it can occur in patients receiving immunosuppressive treatments for other diseases, such as interstitial lung disease\(^1\) and rheumatoid arthritis, as observed in our case\(^6\). Recently, deep dermatophytosis has been reported in healthy individuals with a genetic predisposition to fungal organisms, such as those with autosomal recessive caspase recruitment domain-containing protein 9 (CARD9) deficiency\(^2\) and C282Y mutation\(^7\). According to a recent systematic review, the most common predisposing factor for invasive dermatophytosis is superficial dermatophytosis, followed by solid organ transplantation, topical immunosuppressant use, gene mutation, diabetes mellitus, and trauma.\(^1\) Deep dermatophytosis is classified into three types: (i) Majocchi granuloma, (ii) deeper dermal dermatophytosis, and (iii) disseminated dermatophytosis.\(^6\) This case corresponded to deeper dermal dermatophytosis. In contrast to Majocchi granulomas, it is characterized by a rapidly growing lesion, commonly confined to the extremities without the involvement of other internal organs. Although the mechanism of fungal invasion in the dermis is yet to be clarified, the possibility of follicular invasion\(^7,8\) or direct invasion from the epidermis into the dermis has been raised\(^3,9\). In most cases of deep dermatophytosis, *T. rubrum* is the most common causative agent; however, other species, such as *T. violaceum*, *T. mentagrophytes*, *T. verrucosum*, and *T. ferrugineum*, have also been found.\(^1,7\) There is no established treatment for deep dermatophytosis; however, systemic antifungal drugs, such as terbinafine, itraconazole, and griseofulvin, are usually used. Although the treatment duration differs depending on each patient’s immune status, most patients respond well to systemic antifungal drugs. In a recent study, terbinafine was recommended as the first-line treatment for immunocompromised patients as its administration is safer than azole drugs.\(^10\) However, as resistance to antifungal drugs has increased recently, identifying the causative fungal patho-
gen is crucial. Combined treatment with multiple antifungal agents should be considered when genetic abnormalities, such as CARD9 deficiency, are present¹. In this case report, before the pathogen was identified, the patient’s systemic condition deteriorated rapidly. Therefore, systemic antibiotics and amphotericin B were simultaneously administered, and the skin lesions improved. Deep dermatophytosis can easily be mistaken for another disease, as it appears in various clinical manifestations. If treatment is delayed, immunocompetent patients can progress to a severe disease course, such as hematogenous dissemination. Hence, clinicians should differentiate this disease and conduct treatment at an appropriate time. Herein, we report a case of deep dermatophytosis in an immunocompromised patient who was successfully treated with amphotericin B.
