= Abstract =

Candidiasis is a common fungal infection that usually affects the oral cavity. It is occasionally difficult to diagnose candidiasis because of its various clinical manifestations. Moreover, chronic inflammation of the lips can obscure clarification of its disease entity in patients with chronic cheilitis. Here we aimed to investigate patients with refractory chronic cheilitis who were initially diagnosed with candidiasis. We screened patients with lip lesions that were clinically suspected to have candidiasis. Our two 65-year-old patients with refractory chronic cheilitis were initially diagnosed with candidal infection. Punch biopsies were performed of the lesions and a diagnosis of actinic cheilitis was made in both patients. Since we did not note prominent improvement after conservative treatment and cryotherapy, we applied 0.015% ingenol mebutate gel for further treatment and then observed significant improvement.

[Key Words: Actinic cheilitis, Candidiasis, Ingenol mebutate gel]

INTRODUCTION

Candida is a genus of yeast and usually a commensal organism in humans. However, it occasionally causes various clinical signs and symptoms depending on the infected anatomical location. Oral candidiasis, the most common fungal infection in humans, involves lip manifestations. Angular cheilitis is a typical lesion that is derived from the inflammation of Candida-affected lips. However, Candida-associated lip lesions can appear at both the corners of the mouth and the mid-portion of the lips. Thus, it is sometimes difficult to distinguish it from other diseases involving lip inflammation, such as actinic cheilitis (AC).

AC, a major precancerous lesion of the lip, is considered an actinic keratosis on the lip and can progress to squamous cell carcinoma (SCC). Therefore, early detection and proper treatment are important.

Here we reviewed the medical records of patients with chronic cheilitis who visited our dermatology clinic. We found two cases of refractory chronic...
cheilitis that were initially assessed as *Candida*-associated lesions. Here we report our experience with chronic cheilitis cases that were reassessed and managed after histological examinations.

**CASE REPORT**

**Case 1**

A 65-year-old woman presented with an erythematous and whitish plaque with crusting and erosion on the lower lip that had persisted for several months. There was a white pseudomembranous patch on the lower lip at the initial visit, and oval budding cells were observed in a potassium hydroxide (KOH) smear. She had no specific medical history other than hypertension controlled by medication. We prescribed itraconazole 200 mg/day for 2 weeks according to a clinical diagnosis of candidiasis. The pseudomembranous patch disappeared after antifungal treatment; however, the underlying crusting and erosive lesions persisted (Fig. 1A).

A punch biopsy was performed. In the pathologic examination, the epidermis showed hyperkeratosis and acanthosis with cytologic atypia in the basal cell layer. Solar elastosis and moderate infiltration of inflammatory cells were observed in the dermis (Fig. 2A). There were no observed microorganisms on periodic acid-Schiff (PAS) staining (Fig. 2B). Based on the histologic findings, AC was diagnosed.

Cryotherapy was performed; however, no clinical improvement was noted. For further treatment, we applied 0.015% ingenol mebutate (IM) gel once daily for 3 days. Because there was insufficient information about its local skin reaction (LSR) on the lip, the application was performed in a restricted area (Fig. 1A, white dotted line). We created a physical barrier with antimicrobial ointment surrounding the treatment area to minimize the LSR and prevent flow of the IM gel into the intraoral cavity.

![Fig. 1. Clinical photographs of case 1 (A) Erythematous whitish plaque on the lower lip with crust and erosion (white dotted line indicating the area to which the ingenol mebutate gel was applied.) (B) At 4 weeks after application: The yellowish crust and erosion has disappeared. (C) At 12 weeks after application.](image-url)
At 4 weeks after treatment, clinically significant improvement was observed in the treated area. The crusts and erosions disappeared but the erythema with dead skin remained (Fig. 1B). At 12 weeks after treatment, however, a mild crust developed (Fig. 1C). The LSR was tolerable and we planned to apply IM gel to the extended area. However, the patient did not return for follow-up.

**Case 2**

A 65-year-old man presented with an ulcerative plaque and crusting surrounded by a yellowish-white keratotic rim on the lower lip. Symptoms waxed and waned over several years' time (Fig. 3A). A KOH smear was conducted of the yellowish-white rim and assembled yeast-like cells with pseudohyphae were observed. He had no specific medical history. We prescribed itraconazole 200 mg/
day for 2 weeks according to the clinical diagnosis of candidiasis. However, no clinical improvement was observed.

A punch biopsy was performed. On the pathology examination, hyperkeratosis, acanthosis, and mild basal cell atypia were observed in the epidermis with lichenoid infiltration of the papillary dermis (Fig. 2C). No fungal material was seen on PAS staining (Fig. 2D) and a diagnosis of AC was made.

Because the lesion did not respond to cryotherapy, we applied 0.015% IM gel for 3 days on all of the erosive and crusty surfaces. We created a barrier with antibiotic ointment as described in case 1. At 8 weeks, partial improvement was noted but the erosion and crusting persisted (Fig. 3B). At 12 weeks after treatment, the lesion widened (Fig. 3C) and we reapplied the IM gel. At 8 weeks after the second application, the lesion had decreased in size but complete remission was not achieved (Fig. 3D).

**DISCUSSION**

Cheilitis can be classified by its causative factors. For example, sun exposure induces actinic cheilitis, inflammation of the minor salivary glands causes
cheilitis glandularis, continuous physical damage can induce exfoliative cheilitis, an allergic reaction causes contact cheilitis, and a candidal infection can cause angular cheilitis. Angular cheilitis is an inflammatory condition of the corners of the mouth that is caused by infection, irritation, or allergies, and Candida is one of the major infection sources. Candidal infection, however, occasionally occurs on the mid-portion of the lip as well as the corners of the mouth. In the present cases, there was a concomitant fungal infection on the existing AC lesions that prevented a precise evaluation at the first assessment.

AC is a precancerous condition of the lip that can progress to SCC, which has a higher risk of metastasis and disease-specific death than SCC at other locations. Therefore, early detection and effective treatment of AC are important. Surgery, cryotherapy, topical 5-fluorouracil, topical imiquimod, and pulsed carbon dioxide laser are possible treatments of choice; however, unsatisfactory responses and recurrences are common. Photodynamic therapy is reportedly an effective and safe modality that can be used in field therapy. However, it is not always available.

IM, a plant extract from Euphorbia peplus, has been used as a traditional medicine by Australian aborigines to treat skin lesions. Two concentrations of IM gel were approved for the topical treatment of actinic keratosis by the US Food and Drug Administration in 2012: 0.015% for facial lesions and 0.05% for lesions on the trunk or extremities. Although the exact mechanism of action of IM is not fully understood, it is thought to have a dual mechanism consisting of rapid lesion necrosis followed by a lesion-specific immune response. Treatment trials with IM gel have been performed for AC in Europe, but there are no reports from Asian countries, including Korea.

**Fig. 4.** Local skin reactions in two patients (A) shows case 1. (B) and (C) show the first and second treatment reactions in case 2. (A) At 2 days after application: The erosion and mild exudate are limited to the treated area. (B) At 4 days after application: Erosion with crusts and mild bleeding are visible. (C) At 4 days after application: Erosion and mild crusts are visible.

Since IM gel was originally used to treat actinic keratosis based on the concept of field therapy, its use could be effective in wide AC lesions. However, considering the anatomical features noted in these
cases, namely a thin epidermis and inner mucous membrane of the lip, we were concerned about a severe LSR and the flow of IM gel into the oral cavity. Therefore, we used 0.015% IM gel as spot therapy with a physical barrier.

Six of 12 previously reported cases showed complete clearance of the AC lesion after treatment with IM gel. Most LSR were tolerable and resolved within 1–2 weeks. Some patients, however, complained of pain and severe discomfort when eating and one showed an intolerable LSR involving >50% of the lower lip.9-11

The LSR was tolerable in each of our cases (Fig. 4). However, patients did not show a sufficient response compared to those in previous reports. The local treatment regimen and relatively small amount of gel applied compared with that used in actinic keratosis cases are possible contributing factors. We planned to apply IM gel in a sufficiently wide area to obtain a satisfactory outcome; however, neither patient attended followed-up sessions.

In conclusion, coexisting candidiasis or the development of normal flora in the oral cavity can occur in cases of cheilitis. Furthermore, reassessment by histopathological examination is required to ensure diagnostic accuracy in cases of refractory cheilitis. In addition, IM gel showed acceptable therapeutic effects and a tolerable LSR in the treatment of AC.
